

### ***E-94-016: Measuring Rare Radiative Decays of the Phi Meson***

The study of the radiative decays of the heavier vector mesons,  $J/\psi$  (charmonium:  $c\bar{c}$ ) and  $\Upsilon$  (bottomonium:  $b\bar{b}$ ), soon after their discovery, played an important role in understanding quarkonium spectroscopy. Interestingly enough, although the  $\phi$  (strangeonium:  $s\bar{s}$ ) was discovered earlier, much less is known about its radiative decays. One can enumerate seven energetically allowed decays  $\phi \rightarrow X \gamma$ , where  $X$  is a particle. Only two have been observed:  $\phi \rightarrow \pi^0 \gamma$  and  $\phi \rightarrow \eta \gamma$ . Although phase space would favor the former, the branching ratio for the latter is greater by an order of magnitude, reflecting the  $s\bar{s}$  contribution to the quark content of the  $\eta$ . Two of the energetically allowed decays,  $\phi \rightarrow \rho \gamma$  and  $\phi \rightarrow \omega \gamma$  are forbidden since they are C-violating. However, the experimental limits on the branching ratios ( $< \text{few percent}$ ) for these modes are poorly determined. Another allowed decay involves a pseudoscalar:  $\phi \rightarrow \eta' \gamma$ , as yet unobserved, should provide information on the quark/gluon content of the  $\eta'$ . Radiative  $\phi$  decays into the isoscalar  $f_0(980)$  and isovector  $a_0(980)$  could shed light on the substructure of these states. Originally assigned to the scalar nonet, there is mounting evidence that these are not  $q\bar{q}$  states. There is much theoretical speculation about what these states might be and possible interpretations include four-quark states and molecular states ( $K\bar{K}$ ). The measurement of the ratio:  $(\phi \rightarrow a_0 \gamma)/(\phi \rightarrow f_0 \gamma)$  should allow one to select among interpretations. The decays into these scalar states are also important since they provide information on  $\phi \rightarrow K_{\text{short}} K_{\text{long}} \gamma$ , a potentially insidious background to CP-studies at an  $e^+e^- \phi$  factory if the very low energy radiated photon goes undetected. A  $\phi$  factory is predicated on a correlated source of neutral kaons since  $\phi \rightarrow K_{\text{short}} K_{\text{long}}$ .

Up to now, information on radiative decays comes from  $e^+e^- \rightarrow \phi \rightarrow X \gamma$  and one of the reasons for the paucity of data on these radiative decays is that the radiated photon is low in energy ( $E_\gamma$ ). Incidentally, the decays  $V \rightarrow P \gamma$  and  $V \rightarrow S \gamma$  (where  $V$  = vector,  $P$  = pseudoscalar and  $S$  = scalar) are E1 or M1 transitions and the resulting  $E_\gamma^3$  strongly damps the decay rate. At CEBAF, the photoproduction process will be used in this experiment to produce a fairly well collimated source of  $\phi$ 's, defined in energy and with a rate ( $\sim 30 \phi/\text{sec}$ ) comparable to an  $e^+e^-$  luminosity of  $10^{31}/\text{cm}^2/\text{sec}$ . This is comparable to what is currently available in colliders but the boost factor (as high as 12 for 6 GeV electrons) provides an important advantage. This experiment will use the tagged photon beam in Hall B. Photons in the range from 4 to 6 GeV will be incident on a Be target. A 624-element lead glass detector will be used to look at decays:

$\phi \rightarrow \pi^0 \text{ (or } \eta) \gamma \rightarrow 3 \gamma$

$\phi \rightarrow \omega \gamma \rightarrow \pi^0 \gamma \gamma \rightarrow 4 \gamma$

$\phi \rightarrow f_0 \gamma \rightarrow \pi^0 \pi^0 \gamma \rightarrow 5 \gamma$ ; and

$\phi \rightarrow a_0 \gamma \rightarrow \pi^0 \eta \gamma \rightarrow 5 \gamma$

Branching ratio sensitivities of  $10^{-4}$  to  $10^{-5}$  for the latter two modes can be achieved. These measurements will complement measurements in future  $\phi$  factories, where the backgrounds and systematics are far different.

The experiment will be located in Hall B either in front of or in back of the CLAS detector and will likely run sometime in 1997.
